Proteinuria and hematuria are the most often found symptoms of renal disease. Recently we have learned that urine protein patterns mirror the sites and mechanisms of the events.

Renal dysfunctions are excluded with high certainty when cystatin C in serum, total protein, albumin and α_1 -microglobulin, hemoglobin and leucocyte esterase excretion are normal (1,2).

Figure1 shows the strategy as workflow.

Figure 1. Proposed combination for serum and urine screening tests for the exclusion and differentiation of renal diseases.

By quantitating single proteins with different molecular weight (IgG, albumin, α_1 -microglobulin, α_2 macroglobulin) in urine, prerenal forms can be separated from glomerular and tubulo-interstitial (Fig.2) and postrenal ones. Figure 2 shows the differentiation pattern from patients with a primary glomerulopathy, secundary glomerulopathy and patients with a tubulo-interstitial nephropathy.

Figure 2. Urinary α_1 -microglobulin excretion rates in comparison to albuminuria in primary glomerulopathies (1), secundary glomerulopathies (2) and tubulo-interstitial diseases (3) separated by two hyperbolic curves. The two lines characterize the upper reference limits for albumin (20 mg/ g creatinine) and α_1 -microglobulin (14 mg/ g creatinine).

Albuminuria can further be differentiated with regard to selectivity of glomerular barrier, degree of tubular involvement and postrenal contamination. Measuring urine IgG has been found to be helpful in separating primary and secondary glomerular diseases. By calculating the minimal tubular marker excretion due to overload the degree of interstitial

Corrispondenza a: Dott.Walter Hoffman - Istutute for Clinical Chemistry and immunology, Städt. KHS-München Neuperlach, Germany - E-mail: Hofmann-Sedlmeir@t-online.de

involvement in tubular diseases may be calculated (4). Bence-Jones proteinuria is suspected whenever albumin excretion is below 30% of total protein and confirmed by light chain analysis (3).

In case of hematuria α_2 -macroglobulin can be used to identify postrenal bleeding, whenever albuminuria exceeds 100 mg/L. A relation α_2 -macroglobulin/albumin above 2.0 x10⁻² and an IgG/albumin above 20.0x10⁻² is typical for a renal hematuria (Fig.3).

This new strategy for urine proteins combined with the new GFR-parameter, Cystatin C (5) has been adapted to analytical systems. All measured parameters are listed in a medical report (Tab. I).

 Table I. Medical report of urine protein differentiation from the expert system Protis

Interpretation The glomerular filtration rate is reduced

Signature

Nonselective glomerular proteinuria is present. This is to be classified as distinct. Additional, significant tubular proteinuria exists

This constellation is compatible with primary or secondary glomenulopathy. (e.g. glomenulonephritis, diabetic or hypertensive nephropathy). The presence of renal hematuria is highly likely; additional erythrocytes from postrenal sources cannot be ruled out.

08.04.2003

The result interpretation provided by protis is not intended as a substitute for a physician's diagnosis.	Test, Test	Page 1/1

Figure 3. Comparison of IgG/albumin and α_2 -macroglobulin/albumin ratios in hematuric urines from patients with renal and postrenal diseases. The two lines separate renal from postrenal bleedings.

By linking the analyser to the laboratory computer system, a test strategy can be applied which allows to quantitate the whole range of existing urine protein concentrations from undiluted urine. Serum parameters and the complex urine protein pattern is transferred to the expert system *Protis* (Dade-Behring), which compares the individual results with the knowledge base built from over 500 histological and clinically proven cases (6).

It is to be hoped, that renal diseases can be detected already in a stage where a preventive therapy is still effective. Moreover, application of this strategy can help to prevent many invasive investigations like biopsies, cystoscopies and X-ray investigation.
